Introduction to Memory

- Many different types of digital memory exist – each has a use based on its latency (how long it takes to access data) and cost.

Flash Memory

- Flash memory is a low-latency storage medium which has made massive storage and market gains in the past decade.

Flash Memory

- Flash memory's high density, low latency, and decreasing cost have made it important in all types of computing.
- However, flash memory has been scaled to its fundamental limits. Further progress depends on using 3D integration to increase density.

Motivation

- Novel memory devices must be investigated to continue increasing memory density.
- Resistive random access memory (RRAM) is the leading candidate to replace flash.

RRAM Characteristics

- RRAM is a broad classification which covers many types of memory.
- The commonality between all types is that information is stored by resistance.

Nonvolatile Memory

RRAM Characteristics

- A passive circuit element which changes resistance depending on how it has been biased was first proposed by Chua in 1971.
- This circuit element was named the “memristor,” a portmanteau of “memory” and “resistor.”
- Each element of an RRAM array can be seen as an individual memristor.

Source: Chua, et al.

RRAM Characteristics

- As a two-terminal device, the current traveling through the device must be able to either change or read the memory state.
- RRAM can be bipolar, requiring opposite polarity set and reset, or unipolar, requiring a higher current to reset than set.
- One major hurdle in RRAM is making well-behaved devices which form and deform at a set voltage, and give a reliable resistance state.

Acharyya, et al.

Resistance Changing Materials

- Many transition metal oxides (TMOs) exhibit a change in resistance after a voltage is applied.

- Charged vacancies or interstitials in these materials induce changes in the valence band of nearby atoms.
- Additional electrons are freed, increasing local conductivity.
- Through controlled generation and migration of conduction-inducing defects, the resistivity of the material can be controlled.

TiO₂ – A Model Material

- Among TMOs, titanium dioxide (TiO₂) is one of the most favored resistance switching materials.
- Characterization efforts have focused greatly on TiO₂; its resistance change mechanism is now better understood than in most materials.

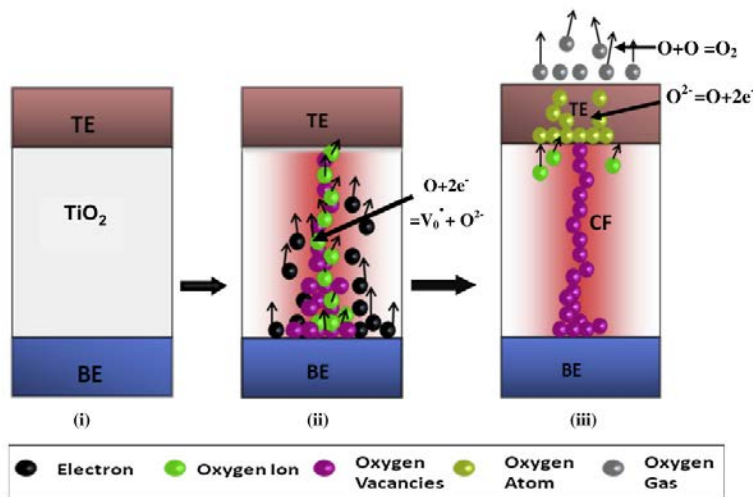

Acharyya, et al.

- A reduction-oxidation reaction can cause an oxygen atom to be removed from the lattice.
- This leaves behind a conductive vacancy.
- In bulk, oxygen deficient titanium oxide is called a Magnéli phase.

TiO₂ – A Model Material

- Through a combination of electrical and thermal effects, oxygen vacancies can arrange in the material and form conductive pathways.
- These effects include electric potentials, electric kinetic energy, concentration gradient, and thermal gradients.

Acharyya, et al.

Yang, et al.

TiO₂ – Electroforming

- In order to create conductive vacancies, a TiO₂ film must undergo an initial electroforming stage.
- This electroforming stage requires high fields and generates oxygen, which can destroy electrodes as it outgases.

Kwon, et al.

- Designing a structure which does not require electroforming would benefit RRAM's reliability and uniformity.

TiO₂ – Electroforming Free Devices

- To remove the necessity of an electroforming step, more complex film stacks are deposited.

Strachan, et al.

- By including a non-stoichiometric film, the vacancies are already created in most of the film
- These vacancies can then move into the insulating layer to create the conducting filaments.

TiO₂ – Set operation

- When a conductive pathway through the film exists, the device is “set.”
- This is done by using an electrical bias to initiate movement of the vacancies through the film.
- When a certain current level is reached, the set operation stops.

Kwon et al.

TiO₂ – Reset operation

- To reset to a high resistance state, another current pulse is used to disrupt the conducting filament.
- High current densities ($>10^6$ A/cm²) in the filament lead to heat, which may be partially responsible for the reset operation.

Kwon et al.

TiO₂ – Variability

- Even in electroforming-free RRAM devices, there is a variation in what set and reset voltages are required.
- Multiple conducting filaments partially form in the insulating film. In each write/erase cycle, a different filament may be conducting the current, leading to variations in resistance.
- Additional impurities can create favorable sites for a filament to form.
- Devices 10 nm wide or less are likely to only contain one filament.

Fabrication - Crossbar Test Structure

- The simplest test device is a crossbar – a bottom and top electrode, with the film being investigated inbetween them.

RIT RRAM Investigation

- A process at RIT was needed to fabricate memristive devices.
- Once this process was proved with a simple structure, it could be used to investigate different material combinations.
- Over the last year, a self-aligned process to create memristors was investigated. However, this process was found to be problematic.

RIT RRAM – Self-Aligned Process

- The self-aligned process left a memristive layer in between the bond pad and bottom electrode.
- Grazing-angle deposition yielded films which were very difficult to control in thickness and uniformity.

RIT RRAM – Current-Voltage Characteristic

- Several program/erase cycles were observed.
- A new process was required to create devices which would have better set/reset behavior, carry higher current, and use lower voltages.

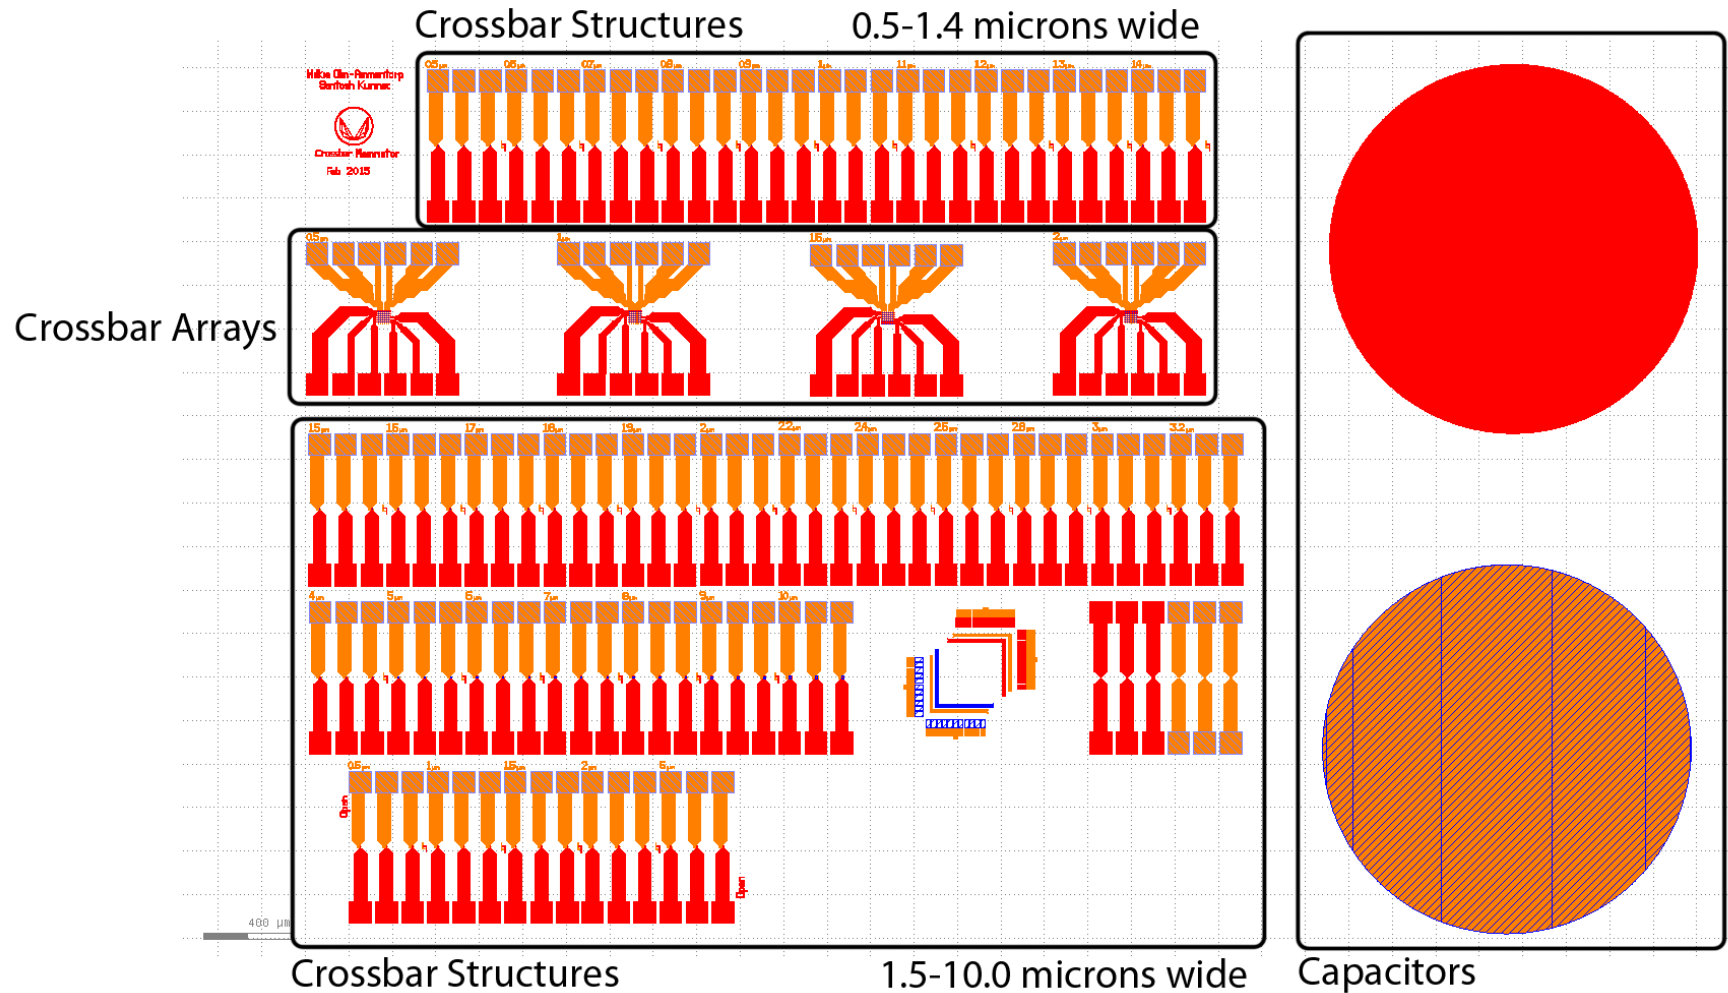

RIT RRAM – New process

- A new process and mask design were created to avoid the previously encountered issues.
- Conventional patterning via lift-off or etch instead of shadow deposition was used.
- An additional insulating layer to prevent unintentional leakage paths was added.
- New process can support many different oxides and metals, deposited with different techniques.

Mask Design

Mentor Graphics Pyxis used to design

Side-profile process summary

Reactive sputter TMO

- In a normal sputter, a noble gas is used to bombard the target.
- By partially using a reactive species such as oxygen, a different material (such as TiO_2 from Ti) can be deposited.
- An experiment was carried out to determine what partial pressure of oxygen would yield conductive and insulating phases of $\text{Ti}_x\text{O}_{2-x}$

O2 partial pressure (mT)	Ar partial pressure (mT)
0	12
0.2	11.8
0.4	11.6
0.6	11.4
0.8	11.2
1	11
Power	300 W
Time	20 second presputter/ 200 second sputter

Film Characterization

n & k vs. partial oxygen pressure, $\lambda=500\text{nm}$

- Films were characterized by ellipsometry, profilometry, and four-point probe.
- Refractive index of titanium oxides is close to a standard reference ($2.592+0i$)

Pilot Run Current-Voltage Results

- An pilot run of the new process was carried out to create Al/TiO_x-TiO₂/Al crossbar structures.
- Electrical results show that high and low resistance state are possible.

Future Work

- Work is being extended into a thesis, using different electrode and memristive materials.
